17 May 2017

ABSTRACT

Topological connections in the single-streaming voids and multistreaming filaments and walls reveal a cosmic web structure different from traditional mass density fields. A single void structure not only percolates the multistream field in all the directions, but also occupies over 99 per cent of all the single-streaming regions. Sub-grid analyses on scales smaller than simulation resolution reveal tiny pockets of voids that are isolated by membranes of the structure. For the multistreaming excursion sets, the percolating structure is significantly thinner than the filaments in over-density excursion approach.

Hessian eigenvalues of the multistream field are used as local geometrical indicators of dark matter structures. Single-streaming regions have most of the zero eigenvalues. Parameter-free conditions on the eigenvalues in the multistream region may be used to delineate primitive geometries with concavities corresponding to filaments, walls and haloes.

Key words: methods: numerical – cosmology: theory – dark matter – large-scale structure of Universe

1 INTRODUCTION

Large scale structures with highly anisotropic shapes were first theoretically predicted by Zeldovich approximation (hereafter ZA) (Zeldovich 1970). The model based on ZA suggested that the eigenvalues of the deformation tensor dictate the shapes of the *collapsed* structures at the beginning non-linear stage of gravitational instability (Arnold et al. 1982, see also Shandarin & Zeldovich 1989 and Hidding et al. 2014). These structures were found to be crudely characterised as two-, one- and zero-dimensional which actually meant that three characteristic scales of each structure ($L_1 \geq L_2 \geq L_3$) are approximately related as $L_1^{(p)} \approx L_2^{(p)} \gg L_3^{(p)}$ or $L_1^{(f)} \gg L_2^{(f)} \approx L_3^{(f)}$ or $L_1^{(h)} \approx L_2^{(h)} \approx L_3^{(h)}$ respectively. In addition it implied that $L_1^{(p)} \approx L_1^{(f)}$ and $L_3^{(p)} \approx L_2^{(f)} \approx L_1^{(h)}$.¹ At present these generic types of structures are referred to as walls/pancakes/sheets/membranes, filaments and haloes. Although the accuracy of the Zeldovich approximation deteriorates from pancakes to filaments and especially to halos on qualitative level there are no more types of structures. Altogether these structures contain the most of mass in the universe nevertheless they occupy very

little space. The most of space is almost empty and is referred to as voids.

Klypin & Shandarin (1983) (firstly reported in Shandarin 1983) were the first to identify a ‘three dimensional web structure’ in the N-body simulation of the hot dark matter scenario. The simulation with 32^3 particles used Cloud-in-Cell (CIC) technique on equal mesh revealed that the gravitationally bound clumps of mass – haloes in the present-day terminology – were linked by the web of filamentary enhancements of density which spanned throughout the entire simulation box with the side of about $150h^{-1}\text{Mpc}$ in co-moving space. In addition Klypin & Shandarin (1983) suggested that pancakes must be considerably less dense than the filaments since they were not detected in the simulation. These results were quickly confirmed by Centrella & Melott (1983) and Frenk et al. (1983). In addition Centrella & Melott (1983) who ran the simulation on similar mesh but with 27 times more particles also detected pancakes at $\rho/\bar{\rho} = 2$ level. At present this picture is widely accepted, and is referred to as the ‘cosmic web’ (Bond et al. 1996 and van de Weygaert & Bond 2008a).

Galactic distributions in redshift surveys have also revealed distinct geometries and topologies of the cosmic web. One of the first indications of the connection of the clusters of galaxies by filaments was demonstrated by Gregory & Thompson (1978) who discovered a conspicuous chain of

¹ The multi-scale character of the cosmic web was not discussed until 1990s.

2 Ramachandra & Shandarin

galaxies between Coma and A1367 clusters using a sample of 238 galaxies. Later this result was confirmed by de Laparent et al. (1986) who used a significantly greater redshift catalogue of 1100 galaxies of the same region. Zeldovich et al. (1982) compared the percolation properties of the redshift catalogue of 866 local galaxies provided by J. Huchra with three theoretical distribution of particle in space: a Poisson distribution, the hierarchical model by Soneira & Peebles (1978) and the particle distribution obtained from N-body simulation by Klypin & Shandarin (1983). They found that the both the galaxy sample and the density field obtained in N-body simulation percolated at considerably smaller filling factors than the Poisson distribution. On the other hand the hierarchical model percolated at higher filling factors than the Poisson distribution. Further studies confirmed that the galaxies and the particles in the hot dark matter model are arranged in the web-like structures Zeldovich et al. (1982), Shandarin (1983), Shandarin & Zeldovich (1983), Shandarin & Zeldovich (1984). This result was confirmed in more detailed analysis by Einasto et al. (1984). Melott et al. (1983) also found similar percolation properties in the mass distribution in the N-body simulation of a CDM model.

Thus by the early 1990s it was clearly demonstrated that the web like structure is a generic type for a wide range of initial conditions in both two-(Melott & Shandarin 1990, Beacom et al. 1991) and three-dimensional (Melott & Shandarin 1993) cosmological N-body simulations. However it also was demonstrated that the quantitative parameters of the web structures depend on the initial power spectrum. Remarkably the simulations also showed that adding small scale perturbations does not ruin the large scale structures if the slope of the power spectrum is negative in both two- and three-dimensional simulations.

All aspects of these studies have been experiencing great advancements in three decades passed since the discovery and first studies of the geometry and topology of the large-scale structures. The galaxy redshift catalogues have grown by thousands of times (by surveys such as Sloan Digital Sky Survey (SDSS) Tegmark et al. 2003 and Albareti et al. 2016 and the 2MASS Redshift Survey Huchra et al. 2012), the sizes of cosmological N-body simulations (modern large scale simulations like Millennium Springel et al. 2005 and Q-Continuum Heitmann et al. 2015) by more than a million times. The number of various methods for identifying structures has also grown practically from one method² to several dozens (Colberg et al. 2008, Knebe et al. 2011, Onions et al. 2012, Knebe et al. 2013 and references therein). Measuring or quantifying the structures always has been a difficult problem and many sophisticated techniques both mathematically and computationally have been proposed and investigated (see reviews by van de Weygaert & Bond 2008a, van de Weygaert & Bond 2008b).

Cosmic web structures have been characterized using several geometrical and topological indicators such as genus curves (Gott et al. (1986)). In an attempt to characterize the shapes of individual regions in the excursion sets

² FOF was used for the topological studies via percolation technique and identifying super clusters of galaxies (Zeldovich et al. 1982, Shandarin 1983, Shandarin & Zeldovich 1983 on the one hand and for identifying halos Davis et al. 1985 on the other.

of the density field, Sahni et al. (1998) suggested to use partial Minkowski functionals. They developed the method labelled SURFGEN and applied it to CIC density field obtained in N-body simulations (Sathyaprakash et al. 1998, Sheth et al. 2003, Shandarin et al. 2004). Aragon-Calvo et al. (2007) have developed the multi-scale MMF (Multi-scale Morphology Filter) detection technique based on the signs of three eigenvalues of the Hessian computed for a set of replicas of the density field filtered on different scales. Similar multi-scale approaches to identifying structures is adopted in NEXUS and its extensions to velocity shear, divergence, and tidal fields Cautun et al. (2013). More recently, persistence and Morse-Smale complexes in the density fields are analysed by Sousbie (2011), Sousbie et al. (2011a) and Shivshankar et al. (2015) to detect multi-scale morphology of the cosmic web.

There is also an increasing interest in the measures for detecting filaments in large astronomical surveys. Topology in the large scale structure was analysed by Betti Numbers for Gaussian fields (Park et al. 2013) and SDSS-III Baryon Oscillation Spectroscopic Survey (Parihar et al. 2014). Sousbie et al. (2008) detected skeleton of filaments of the SDSS and compared to the corresponding galaxy distribution. In smoothed density of mock galaxy distribution, Bond et al. (2010a) studied the projection of eigenvalues. The Hessian eigenvector corresponding to the largest eigenvalue is used by Bond et al. (2010b) to trace individual filaments in N-body simulations and the SDSS redshift survey data. Majority of the above analyses, however, ignore the dynamical information from the velocity field.

On the other hand, detection of voids and study of their morphological properties are done via numerous methods too. Traditional detection of void regions using just the particle coordinates differ based on the various methods used to identify them (see comparison of void finders in Colberg et al. 2008 and references therein). Some methods involve using under-density thresholds. Blumenthal et al. (1992) proposed that the mean density in voids is $\delta = -0.8$ by applying linear theory argument. Similar threshold was used by Colberg et al. (2005) to identify voids. Under-dense excursion set approach was used by Shandarin et al. (2006) to identify percolating voids. Sheth & van de Weygaert (2004) used the excursion set formalism to develop an analytical model for the distribution voids in hierarchical structure formation (also see the excursion set approaches applied to voids by Paranjape et al. 2012, Jennings et al. 2013 and Achitouv et al. 2015). Voids are also detected by isolating regions around local minima of density fields. For instance, the watershed transform is used by WVF-Platen et al. (2007), ZOBOV-Neyrinck (2008) and VIDE-Sutter et al. (2015) for segmentation of under-dense regions.

The unfiltered density field was generated using DTDE-Delaunay Tessellation Field Estimator (Schaap & van de Weygaert 2000, van de Weygaert & Schaap 2009 and Cautun & van de Weygaert 2011) by applying it to the particle coordinates. Earlier it was shown that DTDE is superior to CIC techniques (Schaap 2007 and van de Weygaert & Schaap 2009) in generation of the density field with high spatial resolution. In a new approach to the analysis of the shapes of the large-scale structures, Sousbie (2011) introduced DIScrete Persistent Structure Extractor (DisPerSE) based on Morse-smale complex. By implementing it on re-

alistic cosmological simulations and observed redshift catalogues Sousbie et al. (2011b) found that DisPerSE traces very well the observed filaments, walls and voids.

An additional dimension to the scope of the structure shapes is related to the question whether the density distribution (regardless of its form: continuous or discrete) is the only physical diagnostic of the cosmic web shapes or not. If not, then whether it is the best of all or not. And even if it is the best, then whether the other fields or distributions can provide a valuable contribution to understanding the shapes of the cosmic web or not. The answer to the latter question seems to be positive. In fact there are examples of attempts to bring new players into the field. For instance Hahn et al. (2007) and Forero-Romero et al. (2009) studied the relation between the geometry of structures and the Hessian of the gravitational potential. Shandarin (2011) demonstrated that the study of the multistream field reveals some features of the structures that cannot be easily seen in the density field. This has become even more evident when Shandarin et al. (2012) and Abel et al. (2012) showed that the full dynamical information in the form of three-dimensional sub-manifold in six-dimensional phase space can be easily obtained from the initial and final coordinates of the particles in DM simulations. Hahn et al. (2015) showed that this method provides extremely accurate estimates of the cosmic velocity fields and its derivatives. It has been shown that the multistream field provides a physical definition of voids in N-body DM simulations by the local condition $n_{str} = 1$ (Shandarin et al. 2012 and Ramachandra & Shandarin 2015). Falck et al. (2012) proposed the ORIGAMI method of assigning particles to structures based on the number of axes along which particle crossing has occurred. Void, wall, filament, and halo particles are particles that have been crossed along 0, 1, 2, and 3 orthogonal axes, respectively. Shandarin & Medvedev (2016) identify the void particles as the ones that do not undergo any *flip-flop* through the evolution. Each of above definitions completely independent of any free parameters, with small differences in the physical implication.

Tracing the Lagrangian sub-manifold also provides rich insights into caustics (Arnold et al. (1982) and Hidding et al. 2014) and halo collapse Neyrinck (2015). Recently, there are attempts to improve N-body simulations (see Hahn et al. (2013), Angulo et al. (2013b), Angulo et al. (2013a), Sousbie & Colombi (2015) and Hahn & Angulo (2016)) by solving the Vlasov-Poisson equation using tessellations in the Lagrangian sub-manifold. Galaxy evolution and star formation in the context of multi streaming phenomenon are studied by Aragon-Calvo et al. (2016).

Despite the considerable improvements in simulating, identifying and measuring the cosmic web – briefly discussed above – many aspects remain unsettled and are vigorously debated. The intention of this work is to further investigate the strengths and weaknesses of the multistream field as a complimentary diagnostic of the shapes in the DM web. Multi-stream field is simply the number of DM streams at every point of Eulerian space. Thus it is an odd positive integer at a given point (Arnold et al. 1982, see also Shandarin & Zeldovich 1989 and Hidding et al. 2014). We estimated it on a regular mesh of a chosen resolution from the tessellation of the simulation particles in Lagrangian space and the particle coordinates at a chosen time Shandarin et al. (2012). The external boundaries of the cold DM web are

the caustics in the density field which are clearly seen in the simulations with adequate resolution of the density field (see e.g. Fig 7 in Hahn et al. (2015)). However the exactly same boundaries of the DM web can be identified as the boundaries of a single-stream flow which is a local parameter. The multistream field even a better indicator of the boundaries of the DM web than caustics because caustics are present everywhere the number of streams varies (from 1 to 3, from 3 to 5, etc) but the boundary of the web are only the one where the number of stream changes from 1 to 3.

In particular we would like to discuss the differences in defining voids in density and multistream fields. It is closely related to the definition and distinguishing of linear and non-linear structures or regimes. One simple statistical definition that often used is as follows: after defining the std of the density contrast $\sigma_\delta \equiv \langle (\rho(x)/\bar{\rho} - 1)^2 \rangle^{1/2}$ one can roughly separate the linear and non-linear regimes by the boundary $\sigma_\delta = 1$. This is obviously very crude characteristic which does not say much about the geometry and topology of the non-linear structures. The parameter σ_δ is frequently evaluated for filtered fields $\sigma_\delta = \sigma_\delta(R_f)$. Unfortunately the transition from ‘non-linear’ field at small R_f to ‘linear’ field at large R_f is smooth and thus choosing a particular value of R_f is remarkably subjective.

A related but different question is how to select individual non-linear structure, like halos, filaments and walls by using a local parameter. In particular the density threshold has been used on numerous occasions especially for identifying halos and voids. As a rule the choices of particular values have not been justified by solid physical evidences. The virial mass and virial radius of a halo are often used as direct indicators of gravitationally bound objects but they are determined by a nonlocal quantity – the mean overdensity of the halo. An interesting comparison of several kinds of boundaries of halos was provided by More et al. (2015). In particular they considered the virial radius R_{vir} , R_{200m} , the splashback radius R_{sp} , and R_{infall} . The splashback radius is defined as an average distance from the center of the halo to the most external caustic if it was resolved. The authors argue that it is “a more physical halo boundary choice” than “commonly defined to enclose a density contrast $\Delta_{m,c}$ relative to a reference (mean or critical) density. This is the boundary where the number of streams falls from three to one in the multistream field.

Gravitationally bound structures could be defined as linear in the sense that $\delta(\mathbf{x}) \ll 1$ for all points in the structure. A simple example is a progenitor of large halo at linear stage. However one cannot accurately identify such an object at linear stage using a local criterion like a density threshold. Even at the nonlinear stage of N-body simulation one cannot predict when a particular fluid element with a given value of δ in a void will be accreted to a wall or filament. Among other factors the size of the void and proximity to a wall would play significant roles. In addition the walls accrete expanding fluid elements as well thus the velocity divergence on the fluid element would not help.

The rest of the paper is organised as follows: we describe the cosmological simulations in Section 2. Some of the important features of the multistream field are described in Section 2.1. Topology of the single-streaming voids is discussed in 3 and that of the multistream structure is investigated using percolation theory in Section 4. . Discussion of

Table 1. Parameters for the simulation boxes: Side length L , number of particles N_p , mass of each particle m_p , and the gravitational softening length ϵ for the GADGET simulations are shown.

L	N_p	m_p	ϵ
$100h^{-1}\text{Mpc}$	128^3	$3.65 \times 10^{10} h^{-1} M_\odot$	$20h^{-1}\text{kpc}$
$100h^{-1}\text{Mpc}$	256^3	$4.57 \times 10^9 h^{-1} M_\odot$	$10h^{-1}\text{kpc}$

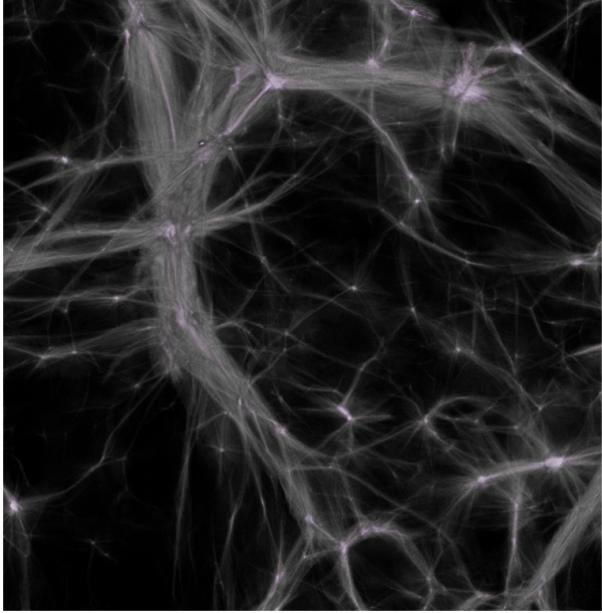

Figure 1. 3D rendering of the multistream field: the cosmic web structure of a $50h^{-1}\text{Mpc} \times 50h^{-1}\text{Mpc} \times 50h^{-1}\text{Mpc}$ slice in a simulation box of side length $100h^{-1}$ Mpc and 128^3 particles. The multistream field is calculated at 8 times the native resolution. void(black) is a percolating structure with $n_{str} = 1$. Regions $n_{str} \geq 17$ show a filamentary structure (gray) and the bright spots at the intersections of the filaments are regions with $n_{str} \geq 100$.

the local geometry of multistream field using Hessian matrices is done in Section 5.

2 THE SIMULATION

In this analysis, we use cosmological N-body simulations generated by the tree-PM code GADGET-2 (Springel 2005 and Springel et al. 2001). The periodic side lengths L , number of particles N_p , masses of each particle m_p and the gravitational softening length ϵ for the two simulations are tabulated in Table 1. Initial conditions at redshift of $z_{ini} = 80$ are generated by MUSIC (Hahn & Abel 2011) with the transfer function from Eisenstein & Hu (1998). We adopt the ΛCDM cosmological model with cosmological parameters $\Omega_m = 0.276$, $\Omega_\Lambda = 0.724$, the Hubble parameter, $h = 0.703$, the power spectrum normalization, $\sigma_8 = 0.811$ and the spectral index $n_s = 0.961$.

2.1 Multi-stream field at $z = 0$

The multistream field objectively characterizes the level of non-linearity in the cosmic web. The ‘number-of-streams’ field or $n_{str}(\mathbf{x})$ is computed from the Lagrangian sub-manifold $\mathbf{x}(\mathbf{q})$, which is a continuous three-dimensional sheet in a six-dimensional (\mathbf{q}, \mathbf{x}) space. In this paper, we utilize the tessellation implementation by Shandarin et al. (2012) to calculate the multistream flow field on the GADGET-2 snapshot at $z = 0$. This implementation only requires initial and final coordinates of the dark matter particles.

The $n_{str}(\mathbf{x})$ values are mostly odd-numbered since each folding in the Lagrangian sub-manifold results in an increase of n_{str} by 2. Exception to this are only at caustics - which have volume measure zero, then the n_{str} is even-valued number. The particles in $n_{str} = 1$ have not experienced orbit crossings and thus these regions are unambiguously identified as void (Shandarin et al. 2012). Foldings in the Lagrangian sub-manifold generally occur one-by-one. For example, a contour of $n_{str} = 7$ will be within a region of $n_{str} \leq 5$. Hence the multistream field commonly has nesting shells, i.e., $3 \supseteq 5 \supseteq 7 \supseteq 9 \supseteq 11 \dots$. Some of the important features of the multistream field are discussed in Appendix A.

The first non-linear DM structures that reach non-perturbative stage of gravitational evolution have $n_{str} = 3$. By visual inspection, these regions generally form a fabric-like open structures that resemble walls. N-body simulations suggest that a DM fluid element after the first crossing of a caustic never returns in a single-streaming state. Therefore the *local* condition $n_{str}(\mathbf{r}_{f.e.}) \geq 3$ (where $\mathbf{r}_{f.e.}$ is the position of the fluid element) is sufficient for the fluid element to be bound to the DM web.

All particles that have fallen into a wall will never return to any single-streaming regions, therefore they can be labeled as gravitationally bound to pancakes/walls. The surface contours of higher n_{str} are embedded within the walls. Figure 1 shows a filamentary structure of the multistream web at $n_{str} \geq 17$. The figure also shows regions around local maxima of the multistream field, which are generally located at the intersections of filaments.

The multistream field can be computed at arbitrary resolutions of diagnostic grids. The parameter ‘refinement factor’ denotes the ratio of separation of the particles in Lagrangian grid, l_l , to side length of diagnostic grid l_d . In a simulation of 128^3 particles, for instance, multistream field computed on a diagnostic grid of size 256^3 would have a refinement factor of $l_l/l_d = 2$.

3 VOIDS IN THE MULTISTREAM FIELD

Gravitational instability results in movement of the collision-less fluid particles in the Universe from voids to walls, walls to filaments, and filaments to haloes. As we mentioned above in the multistream portrait, the entry of mass particles from single-streaming regions into $n_{str} > 1$ region is irreversible. The converse is obviously not true, that is, the particles in $n_{str} = 1$ regions may move to multistreaming region at a later time in the evolution. At a given cosmic time, sufficient condition for dark matter particles to be bound to

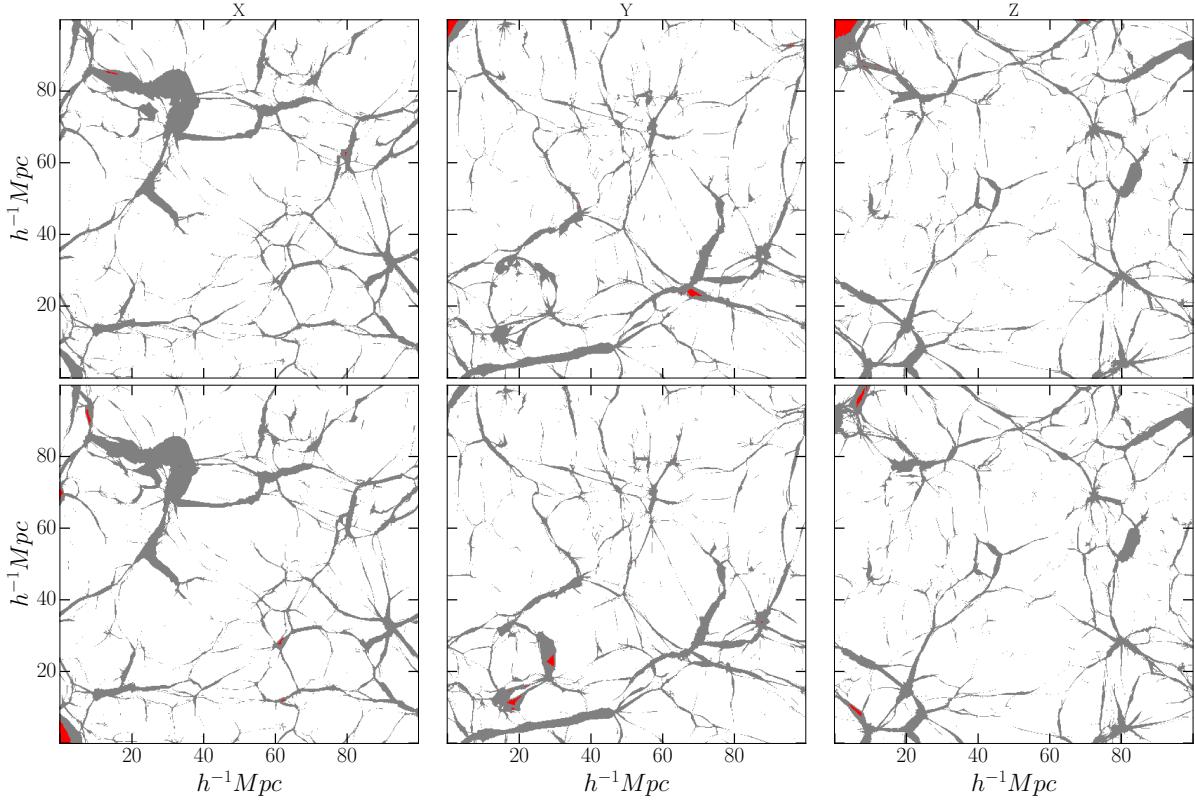

Figure 2. Opposite faces of the multistream field for the simulation box with $N_p = 128^3$. Non-void regions (gray) have $n_{str} > 1$. The largest void (white) in the entire field spans over the entire box. Rest of the smaller isolated voids (red) occupy very small volume fraction.

non-perturbative and non-linear structures like walls/filaments/haloes is being in multistream regions. Therefore, a single-stream flow implies that gravitationally bound structures haven't yet formed, and thus defined as a void region. This definition of void is unambiguous and physically motivated, as demonstrated by Shandarin et al. (2012). It is worth stressing that while the density in voids varies, the number-of-streams is uniformly equal to unity.

For simulation box with 128^3 particles, $n_{str} = 1$ regions have a large volume fraction of $VF_V \approx 93$ per cent regardless of the value of refinement factor (shown in Table 2). Multi-stream web structure in the simulation with higher mass resolution ($N_p = 256^3$) is better enhanced, and the single streaming void occupies around 90 per cent of the volume. Figure 2 shows the single streaming voids occupying large volume of the simulation with 128^3 particles at refinement factor of 4.

3.1 Connectivity of the voids

In order to find whether the void regions of the multistream field are connected or not, we isolate three-dimensional segments with $n_{str} = 1$ and separately label them. The number of disconnected voids in the simulation with $N_p = 128^3$ range from 1 (for refinement factor, $l_l/l_d = 1$) to about 900 (for $l_l/l_d = 8$) as shown in Table 2. Number of isolated voids increases similarly in the simulation with $N_p = 256^3$ particles as well.

Table 2. Volume fraction VF_V of the voids, total number of isolated voids N_V and the filling fraction of the largest void FF_1/VF_V at different refinement factors l_l/l_d . The filling fractions of the largest void at each refinement factor show that most of the $n_{str} = 1$ region is almost entirely a single percolating structure.

N_p	l_l/l_d	VF_V	N_V	FF_1/VF_V
128^3	1	93.46%	1	100%
128^3	2	93.44%	11	99.999%
128^3	4	93.44%	113	99.999%
128^3	8	93.44%	914	99.997%
256^3	1	90.80%	11	99.999%
256^3	2	90.80%	97	99.999%
256^3	4	90.80%	1029	99.997%
256^3	8	90.80%	7259	99.964%

Smoothing of the structure at lower resolution of the multistream field results in increased connectivity of single-streaming regions. In Figure 2, opposite faces on each axes of the multi-field, show a large connected void (white). This means that the largest void percolated throughout the multistream field in all directions. This result is in agreement with Falck & Neyrinck (2015), who studied percolation of

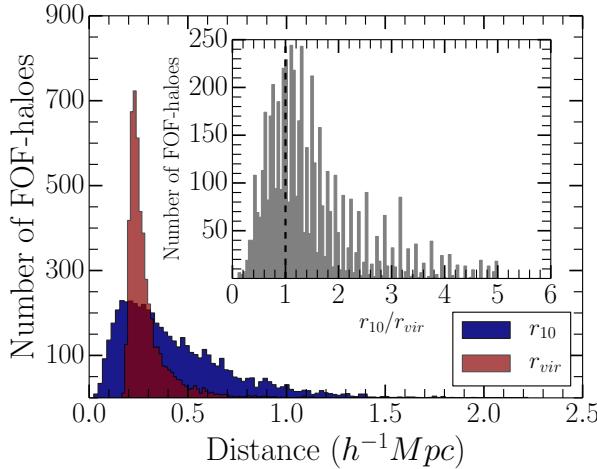

Figure 3. Single-streaming void distribution on diagnostic spheres around FOF-haloes are considered. At radius r_{10} , each diagnostic sphere has $n_{str} = 1$ on 10 per cent of its spherical surface. Distribution function of r_{10} (blue) and FOF-radii r_{vir} (red) are shown. Inner plot shows the distribution function of r_{10}/r_{vir} . The haloes within the dashed line have at least 10 per cent of their virial-surfaces in contact with $n_{str} = 1$ regions.

ORIGAMI-voids in simulations with side lengths of 100 and $200h^{-1}\text{Mpc}$. In addition to the percolating the field, the largest void also fills most of the void volume: the ratio of filling fraction of the largest void FF_1 to the volume fraction of $n_{str} = 1$ regions in the simulation is close to unity (see Table 2). This phenomenon is seen at each of the refinement factors in our analysis. Hence, over 99.9 per cent of the single-streaming sites are connected throughout the simulation box, and they form a single empty region.

As previously mentioned, the multistream web structures of $n_{str} = 3$ form the first gravitationally collapsed structures. These tiny structures are better resolved in higher refinement factors, and they tend to enclose greater number of pockets of single-streaming voids inside them. The red regions in Figure 2 some of the small voids on faces of the simulation box with 128^3 particles. Despite increase in the number of small voids at each of the refinement factors, these void regions (i.e., the single streaming regions excluding the largest void) collectively occupy less than 0.1 per cent of the total void volume in both the simulations. It is also likely that the small voids are simply due to numerical noise. However, the major conclusion regarding small voids remains the same up to refinement factor of 8. We do not pursue further investigation due to tiny effects.

3.2 Halo boundaries within the void

Dark matter haloes are the most non-linear objects in the cosmic web. With the exception of ORIGAMI (Falck et al. 2012), most of the halo finders do not consider multistreaming in the configuration space for finding haloes. Potential haloes found by several such halo finding methods, hence, may have boundaries that intersect with the single-streaming void, which is the least non-linear structure in the dark matter universe. Colberg et al. (2008) even mention existence of ‘void-haloes’ in several halo finder algorithms.

We studied the n_{str} environment of the haloes detected using the Friends-of-Friends method (FOF-Davis et al. 1985) as illustrated in Figure 3. FOF-haloes with more than 20 particles are detected using linking-length of $b = 0.2$ in the simulation with 128^3 particles. We implement the diagnosis method prescribed in Ramachandra & Shandarin (2015): a large number of points are randomly selected on diagnostic spherical surfaces centred at the FOF-centre of the halo. Multi-stream values are iteratively calculated at these spherical surfaces of various radii. We define the distance from centre of a halo, r_{10} , where $n_{str} = 1$ at 10 per cent of the surface of the diagnostic sphere. Distribution of this void-distance parameter is compared to the virial radii r_{vir} of the FOF-haloes. Surprisingly, r_{10} distribution peaks at slightly lower values than the r_{vir} distribution. This implies a large number of FOF-haloes are in the vicinity of the void.

For specific examples of some FOF-haloes, Ramachandra & Shandarin (2015) showed that single-stream may appear within their virial radii too. The distribution of r_{10}/r_{vir} in the inner plot of Figure 3 shows the same phenomenon. The FOF-haloes within $r_{10}/r_{vir} < 1$ (represented by the vertical dashed line) have $n_{str} = 1$ on 10 per cent of their virial surfaces. The figure illustrates that a large number of FOF-haloes satisfy this condition, thus are in contact with the void surfaces. Hence not all the FOF particles have undergone a gravitational collapse during their evolution.

For methods such as FOF, there is no unambiguous linking-length criterion for voids. Similarly for the density fields, a range of under-densities are prescribed by various void finder methods (cf. Colberg et al. 2008). On the other hand, the multistream field unambiguously identifies all the regions without a single gravitational collapse as voids. Haloes detected on the multistream field may address the issue of haloes being in contact with voids.

4 PERCOLATION IN THE MULTISTREAM WEB

A single percolating void fills the $n_{str} = 1$ regions almost entirely, as discussed in Section 3.1. Disconnected pockets of void may exist, but they collectively occupy very small volume fraction (less than 0.1 per cent of the total volume as tabulated in Table 2). Whereas, the non-void structure in the multistream field has a different topological structure. The regions selected with a lower bound on n_{str} could be isolated (generally for high n_{str} thresholds) or connected in a percolating region (for low n_{str} thresholds). We investigate the topological transitions in these excursion sets of multistream field.

The volume fraction as a function of number-of-streams decreases according to a power law in the $n_{str} > 1$ structure (Shandarin et al. 2012 and Ramachandra & Shandarin 2015 report $\text{VF}(n_{str})$ decreasing as $n_{str}^{-2.8}$ and $n_{str}^{-2.5}$ respectively for their simulations). The volume fraction of the excursion set $f_{ES}(n_i)$ is the ratio of volume of all the regions with a lower bound n_i on the multistream field to the total volume V_{tot} of the simulation box, i.e., $f_{ES}(n_i) = \frac{V_{ES}}{V_{tot}} = \sum_{n_{str} \geq n_i} \text{VF}(n_{str})$. Since volume fraction of the each n_{str} rapidly increases with a decrease in multistream value, so does the f_{ES} .

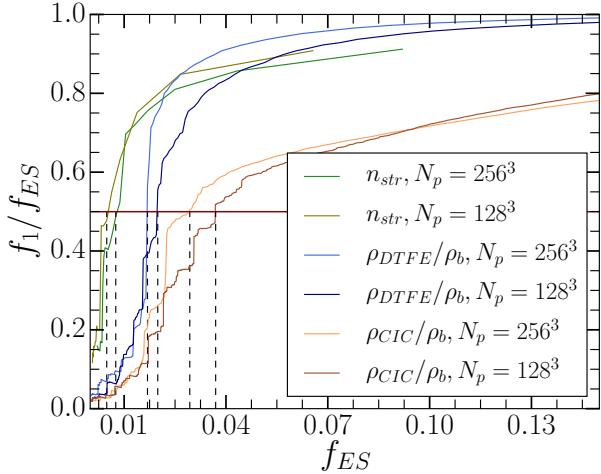

Figure 4. Percolation plot in the multistream field and mass density. Two density estimators - CIC and DTFE are shown. Percolation transition (at $f_1/f_{ES} = 0.5$ shown by the horizontal red line) occurs at smaller excursion set volumes for the multistream field, as seen by the dashed lines for both the curves. It is worth stressing that the percolation curves for n_{str} field are bounded by conditions $f_{ES} < 0.1$.

The excursion set may have number of isolated segments of different volumes. A measure of connectivity in the excursion set regions can be given by the filling fraction, f_1/f_{ES} , where f_1 is the volume fraction of the largest isolated region in the excursion set. f_1 can be computed numerically in the simulations. If the value of f_1/f_{ES} is close to 0, then none of the isolated regions dominate the excursion set. This implies absence of percolation. If f_1/f_{ES} is close to one, it implies a single connected structure dominates most of the excursion set.

The filling fraction f_1/f_{ES} grows from 0 to 1 occurs rapidly f_{ES} during percolation phase transition. A practical robust definition of the percolation transition is at $f_1/f_{ES} = 0.5$, i.e., when the largest region occupies more than 50 per cent of the excursion set volume. The percolation plot in Figure 4 reveals this phenomenon. Excursion volume fraction f_{ES} at this transition, $f_{ES}^{(p)} = 0.48$ and 0.75 per cent for the simulations with with 128^3 and 256^3 particles respectively (although the numbers were obtained in one simulation each. The difference may be well within the range of statistical errors for this size of simulation box). After the percolation transition, the filling fraction of the largest structure stabilizes towards unity.

The nature of the transition in mass density field is similar to that in multistream field. For the simulation simulation with 256^3 particles, the density is calculated using CIC method at 256^3 and 512^3 grid points. In Figure 4, the percolation phenomenon in both mass density fields is shown along with that of multistream fields. The excursion set volume fraction at percolation transition, $f_{ES}^{(p)}$ is lower for multistream field, because the filaments in the multistream field are thinner than that of density picture. Volume fraction of the largest structure detected in the density field also tends to unity with decreasing f_{ES} , albeit less rapidly as that of the multistream field. This means that while the

largest structure in a multistream web occupies most of the structure, the over-density excursion set is more fragmented.

The excursion volume fraction of the multistream web structure is limited to a small fraction of less than 10 per cent since rest of the volume is void. The excursion set volume fraction increases with decreasing number-of-streams and reaches its maximum at $n_{str} = 3$. At this limit the filling fraction f_1/f_{ES} is still less than unity, about 95 per cent. These two peculiar properties of the multistream field explain the shape of the percolation curves in Figure 4. Since the multistream flow field is a discrete data field, the percolation transition is seen to occurs at a particular value of n_{str} rather than a large range of values. For $n_{str} = 17$, the largest structure in the excursion set occupies more than half the volume of the entire excursion set. At this multistream threshold, the largest segment starts spanning large volume of the simulation box (as observed in the left panel of Figure 5). The volume fraction of the excursion set at this percolation transition is $f_{ES}^{(p)} = 0.75$ per cent for simulation with 256^3 particles.

The percolation transition at $n_{str} = 17$ could be used as a criterion for detecting filaments in the cosmic web. Since the largest $n_{str} \geq 17$ region occupies more than 50 per cent of the excursion set, it is essentially the ‘backbone’ of the cosmic web (Shandarin et al. 2010). Heuristic analysis as discussed by Ramachandra & Shandarin (2015) also arrived at the same threshold for identifying filaments. That analysis was based on a multistreams variation in halo environments, hence a local value. From our percolation analysis, we see that it is also justified globally.

In the simulation with 256^3 particles, percolations in the density field occurs at $\rho_{DTFE}/\rho_b = 5.16$ and $\rho_{CIC}/\rho_b = 5.49$ for densities calculated with DTFE and CIC respectively. Here $\rho_b = 256^3/100^3 M_\odot h^{-3} \text{Mpc}^{-3}$, the background density. Notice that these values correspond to the density as calculated by the CIC and DTFE algorithms, and it might be different for other density finding methods. The volume fraction of the excursion set of over-densities at the percolation, $f_{ES}^{(p)} = 2.7$ per cent, is considerably higher than the corresponding $f_{ES}^{(p)}$ value in the multistream field. This implies that the percolation occurs at larger values of filling fraction in mass densities.

5 LOCAL GEOMETRY OF THE MULTISTREAM FIELD

The multistream field has a constant value of 1 for around 90 per cent of the simulation box. At least one gravitational collapse occurs in the remaining 10 per cent of the volume. In these non-void regions, the n_{str} value varies from 3 to very high values, often in the order of thousands. In the multistream field of refinement factor of 2 for simulation with $N_p = 128^3$ particles, maximum n_{str} is 2831. Within the non-void structure, the multistream field may have several local maxima, minima and saddles. Variation of n_{str} is especially high inside halo boundaries, where the particles in their non-linear stage of evolution have undergone a large number of flip-flops.

Local second order variation in a scalar field f like the multistream field can be found using the Hessian matrix

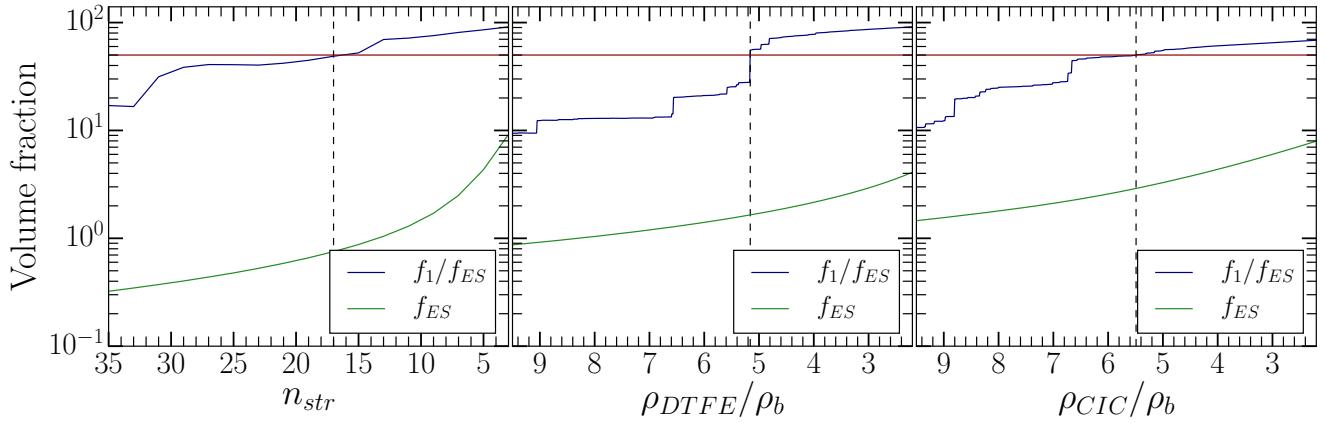

Figure 5. Percolation threshold in the multistream (left panel) and matter density fields. Matter density is calculated using DTFE (middle panel) and CIC (right panel) with a refinement factor of 2 in the simulation with 256^3 particles. The volume fraction of excursion set and the filling fraction of the largest structure is shown. Percolation transition in multistream field at $n_{str} = 17$ is shown by the dashed vertical line. Percolation at $\rho_{DTFE}/\rho_b = 5.16$ and $\rho_{CIC}/\rho_b = 5.49$ are shown by the dashed vertical line.

H(f). An element of the Hessian matrix is given in [Equation 1](#), where i and j can be any of x , y or z directions.

$$\mathbf{H}_{ij}(f) = \frac{\partial^2 f}{\partial x_i \partial x_j} \quad (1)$$

In our analysis, we have chosen $f = -n_{str}(\mathbf{x})$ for understanding local variations of the multistream field. The resulting Hessians at each point on the configuration space are always symmetric matrices, as illustrated in [Appendix B](#). The eigenvalues of these Hessian matrices are always real, and depending on if their values are positive or negative, one may infer local geometrical features in the multistream field.

Within the void, there is no variation in the multistream values. Hessians $\mathbf{H}(-n_{str})$ are zero matrices in large volume fraction of the simulation box (around 90 per cent in both the simulations) due to the constant value of $n_{str} = 1$ in this percolating void. Eigenvalues of these Hessian matrices, sorted as $\lambda_1 \geq \lambda_2 \geq \lambda_3$ are close to 0 at a large number of regions as shown in the top panel of [Figure 6](#). In the simulation with 128^3 particles, the median values of each eigenvalue are 0.09 , -3×10^{-10} and -0.11 for λ_1 , λ_2 and λ_3 respectively. By selecting just the non-void region by $n_{str} > 1$, notably fewer number of eigenvalues have small absolute values. The median values of each of the eigenvalues in the non-void regions are 4.01 , 0.48 , and -0.85 respectively for λ_1 , λ_2 and λ_3 . Bottom panel in [Figure 6](#) shows a significant change in the probability distribution of Hessian eigenvalues around 0, the distribution pattern at the tails are mostly identical to the distribution pattern in the entire simulation box.

A large fraction of eigenvalues in non-void regions are still around 0, but their percentage is quite less compared to that of the entire box. For instance, nearly 66 per cent of λ_1 's, 72 per cent of λ_2 's and 48 per cent of λ_3 's are within in the range of 0.0 ± 0.1 in the entire simulation box. However, with the exclusion of void regions, these volume fractions drops to 0.1, 7.7 and 8.4 per cent respectively ([Figure 7](#)). Hence most of the eigenvalues at the void region have small absolute values.

Hessian eigenvalues in multistream fields differ from that in density, gravitational potential or velocity shear tensor. Constant scalar value of n_{str} facilitates the Hessian $\mathbf{H}(-n_{str})$ matrices to be presumptively close to zero. On the other hand, in density field manifests in a range of low values in the voids, resulting in non-zero Hessian matrices. Eigenvalues of velocity shear tensor do not peak at zero either [Libeskind et al. \(2013\)](#). For the deformation tensor, morphological characterization of the cosmic web using Zel'dovich formalism shows that each eigenvalue must be negative in voids.

The eigenvalues of $\mathbf{H}(-n_{str})$ span a large range of values in our cosmological simulation. The largest eigenvalue of the triplets, λ_1 having large positive values throughout the multistream web structure (see [Figure 8](#)). Absolute values $|\lambda_1|$, $|\lambda_2|$ and $|\lambda_3|$ peak around the neighbourhood of intersections of filaments. These junctions are usually high streaming regions due to shell crossing from multiple directions. [Ramachandra & Shandarin \(2015\)](#) observed that these regions with intersecting filaments are in the vicinity of large FOF haloes.

If the Hessian matrices are positive definite in a region, i.e., if all the eigenvalues are strictly positive, then the interior of this convex region has at-most one minimum. For our choice of $-n_{str}(\mathbf{x})$ as the domain of Hessian, this means that the convex neighbourhoods around local maxima of the multistream field are isolated by the positive definite Hessian matrices. Closed surface contours at high streaming or the most non-linear regions are selected. These regions may indeed be the regions of dark matter haloes.

The smallest eigenvalue, λ_3 has lowest volume fraction of all the eigenvalues in the positive tail of the distributions in [Figure 6](#). Since the condition $\lambda_3 > 0$ ensures the Hessian matrix to be positive definitive, we may use it as a primary criterion in isolating compact regions of dark matter haloes. These regions also roughly correspond to isolated globes as seen in [Figure 9](#). Local geometry analysis is pertinent for halo detection due to compact geometry of the haloes. In principle, other components of the cosmic web could also be detected. Tubular structures in filaments could be detected, as shown in [Figure 9](#), using conditions on the eigenvalues

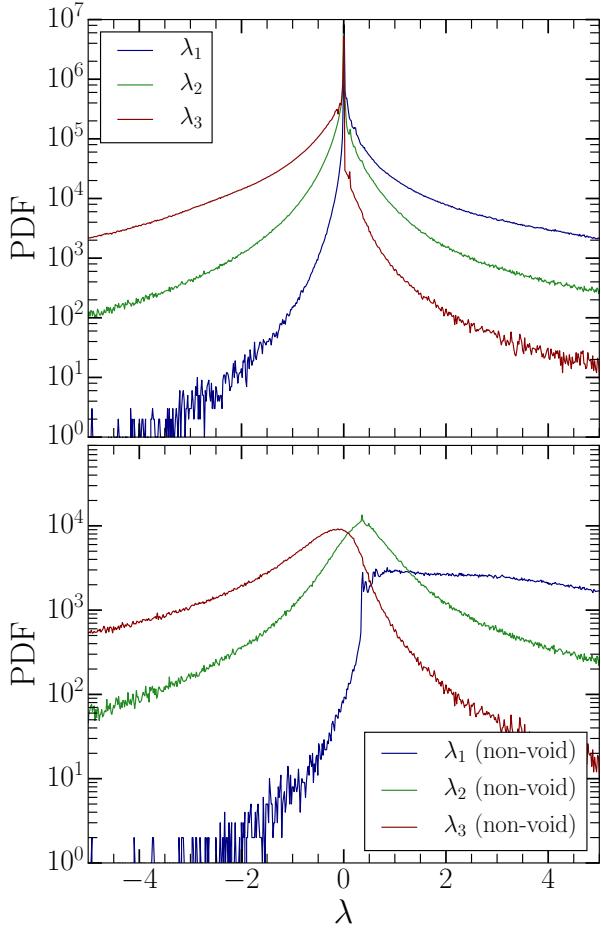

Figure 6. Probability distribution function of the sorted eigenvalues of the Hessian $\mathbf{H}(-n_{str})$ in the simulation box with $N_p = 128^3$. Top panel: Distribution in the entire simulation box. The multistream field is calculated at refinement factor $l_l/l_d = 2$ and smoothing scale of equal to l_d . All the three eigenvalue data fields have a highest number of points where their value is 0. Bottom panel: Hessian eigenvalues for the non-void region ($n_{str} > 1$) is shown. Total number of eigenvalue triplets are less than 10 per cent of that of the full simulation box. Eigenvalues close to zero in non-void regions are notably fewer than in the entire simulation box.

as $\lambda_1 > \lambda_2 > 0$ and $\lambda_3 < 0$. Fabric-thin walls could be detected by $\lambda_1 > 0$ and $\lambda_3 < \lambda_2 < 0$.

5.1 Softening of the multistream field

Hessian eigenvalues are generally defined on continuous functions. Although our domain of the Hessian is an inherently integer-valued field, it describes the multistream structure at the level of diagnostic grid. Hence it may be considered to be numerically equivalent to a continuous function where the numerical approximation of differentiation is a valid operation. This can be verified mathematically by finding that Hessian $\mathbf{H}(-n_{str})$ is symmetric (Appendix B shows the numerical approximation of the Hessian matrix term for generic unfiltered multistream field.)

Smoothing the multistream field (at the refinement level of $l_l/l_d = 1$ or 2) effectively reduces noise. There is

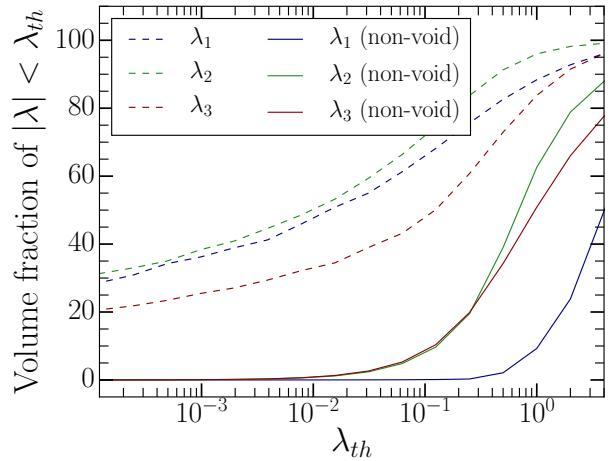

Figure 7. Comparison between small eigenvalues of the multi-stream Hessian $\mathbf{H}(-n_{str})$. Percentage of eigenvalues with absolute values less than a cut-off, λ_{th} are shown for full simulation box (dashed lines) and the multistream web structure (solid lines). The multistream web has fewer eigenvalues below $\lambda_{th} = 0.1$. The void seems to have most of the small eigenvalues.

also a systematic variation in the distribution of smoothed n_{str} values as shown in Figure 10. Volume fraction of the single-streaming voids only varies from 90.8 per cent without smoothing to 89.1 per cent for the Gaussian softening length of $0.39 h^{-1} Mpc$ (twice the length of diagnostic grid l_d). On the other hand, $n_{str} = 3$ regions gain volume fraction from 4.9 per cent in un-smoothed field to 7.1 per cent for $0.39 h^{-1} Mpc$. This is seen in the multistream structures of smoothening scales of $0.39 h^{-1} Mpc$ in Figure 11. Multistream regions with $3 < n_{str} \leq 100$ occupy correspondingly lower volumes for higher smoothing, and the variation is noisy beyond $n_{str} > 100$. Figure 11 shows the multistream field on a small slice of the simulation at different softening scales, and walls and filaments are resolved better with increasing softening.

Smoother multistream fields result in less noisy PDFs of the Hessian eigenvalues. For instance, the volume fraction of regions with positive curvature (i.e. $\lambda_3 > 0$) is 2.4%, 2.3% and 2.5% for scales $0.20 h^{-1} Mpc$, $0.39 h^{-1} Mpc$, $0.78 h^{-1} Mpc$ respectively. Further analysis of smoothed positive definite regions is relevant in determining halo boundaries, and will be extensively discussed in the next paper.

5.2 Resolution dependence

Multi-stream calculation can be done at arbitrarily high resolutions by populating the tetrahedral simplices. For our resolution study, we have chosen a smaller slice of $50 h^{-1} Mpc \times 50 h^{-1} Mpc \times 50 h^{-1} Mpc$ (grid of size 64^3 from the N-body simulation) from the simulation with $N_p = 128^3$ particles. The multistream field is calculated at 4 different refinement factors, i.e., at diagnosis grids of size 64^3 ($l_l/l_d = 1$), 128^3 ($l_l/l_d = 2$), 256^3 ($l_l/l_d = 4$) and 512^3 ($l_l/l_d = 8$) respectively.

Volume fractions of each multistream does not change systematically for different levels of refinement, except at very high n_{str} values (see Ramachandra & Shandarin 2015 for dependence of n_{str} variation on refinement of the diag-

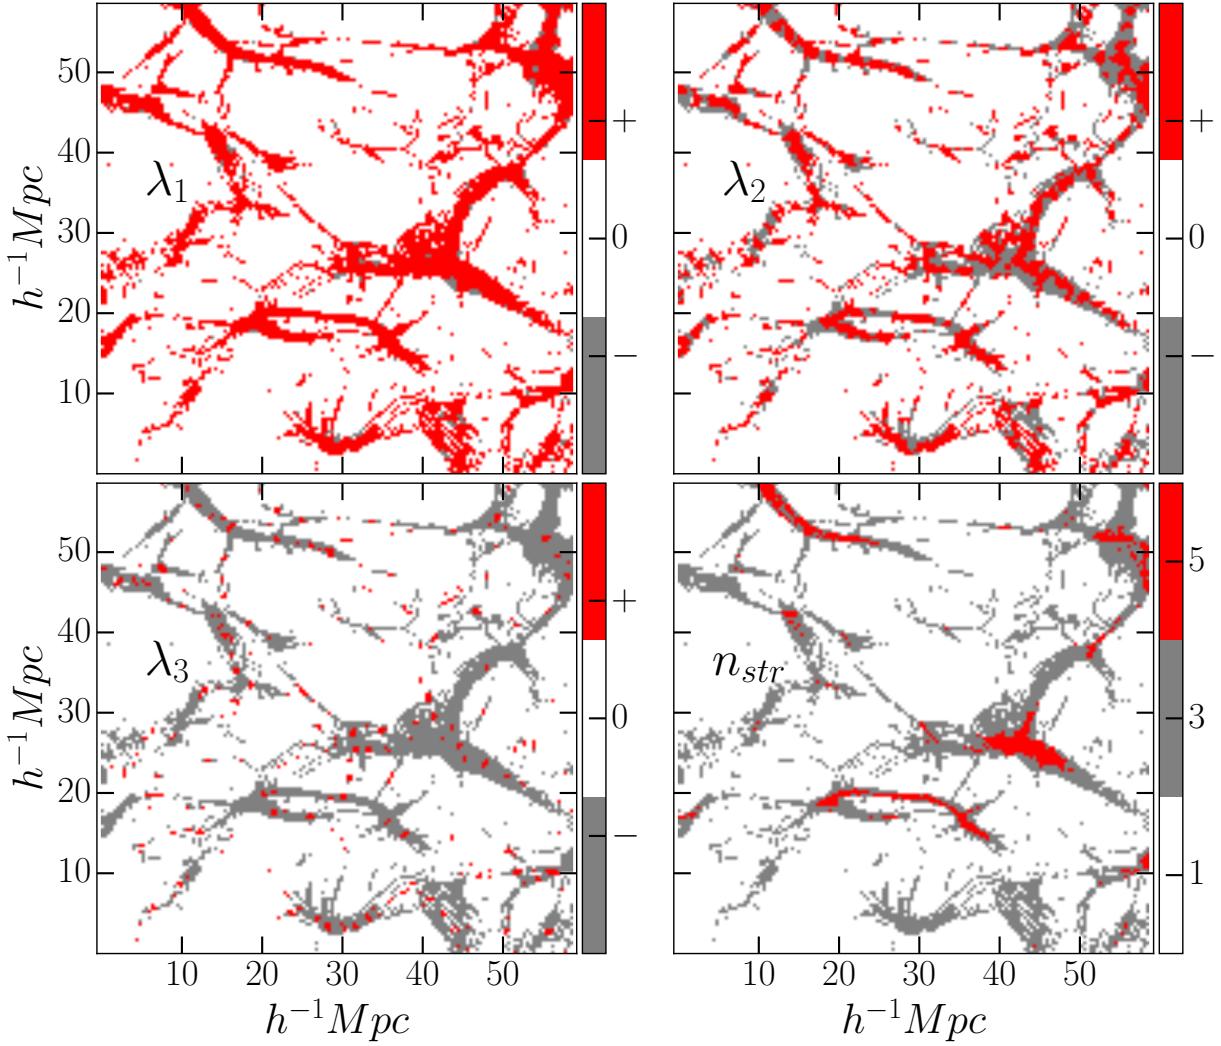

Figure 8. Eigenvalues of the Hessian matrix $\mathbf{H}(-n_{str})$ in a slice of $50 h^{-1}$ Mpc $\times 50 h^{-1}$ Mpc slice of the simulation box of 128^3 particles. Variation in the eigenvalues in the multistream web structure is shown. The largest eigenvalue λ_1 (top left panel) has positive values throughout the structure. The smallest eigenvalue λ_3 (bottom left) has negative values surrounding positive definite regions of the n_{str} field. Corresponding multistream field is shown in the bottom right panel for single, three and more than five streams.

nostic grid). At high multistream values, higher resolutions reveal a considerably less noisy multistream fields.

There are no variations in the volume fractions of the cosmic web components classified using the global n_{str} thresholds as shown in Table 3. Voids ($n_{str} = 1$) occupy about 90 per cent of the volume at each refinement factor. Rest of the heuristic thresholds that identify the structure components (as prescribed by Ramachandra & Shandarin 2015) are constant multistream contours: $3 \leq n_{str} < 17$ for walls, $17 \leq n_{str} < 90$ for filaments and $n_{str} \geq 90$ for haloes. Since the volume fraction of each n_{str} values are about the same at each refinement factor, the volume fraction of the cosmic web components corresponding to global multistream thresholds do not vary considerably.

However, local geometry analysis of the multistream flow field varies considerably on the resolution of the analysis grid. For our Hessian $\mathbf{H}(-n_{str})$, the regions with $\lambda_1 \geq \lambda_2 \geq \lambda_3 > 0$ in non-void regions occupy 1.8 per cent of the entire box in native resolution of diagnostic grid, as shown in

Table 3. Volume fraction (in per cent) of n_{str} thresholds for cosmic web structures as defined by Ramachandra & Shandarin (2015). Multi-stream field is calculated at 1, 2, 4, and 8 times the native simulation resolution of 64^3 grids. Small slice of $50h^{-1}\text{Mpc} \times 50h^{-1}\text{Mpc} \times 50h^{-1}\text{Mpc}$ is chosen for the analysis.

Global thresholds	64^3	128^3	256^3	512^3
$n_{str} = 1$ (Void)	90.87	90.92	90.94	90.94
$3 \leq n_{str} < 17$ (Wall)	8.71	8.66	8.63	8.64
$17 \leq n_{str} < 90$ (Filaments)	0.39	0.39	0.39	0.39
$n_{str} \geq 90$ (Haloes)	0.034	0.035	0.036	0.036

Table 4. This fraction reduces to 1.3 per cent at diagnostic grid of 512^3 resolution. Variations with refinement factors are seen in other eigenvalue conditions in the non-void too: volume fraction of $\lambda_1 > 0 > \lambda_2 \geq \lambda_3$ regions increases from

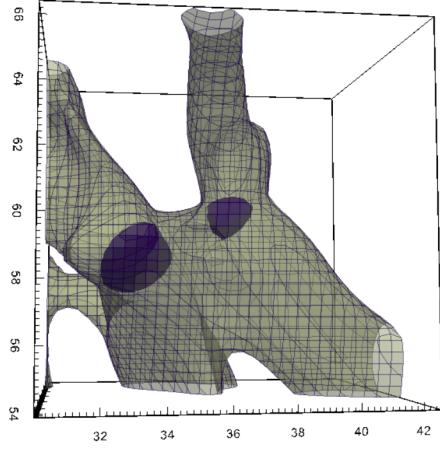

Figure 9. Surfaces identified in the multistream field. Blue regions are closed regions with $\lambda_3 > 0$, which we identify as two haloes. Other surface has an open curvature along one direction, with $\lambda_1 > \lambda_2 > 0$ and $\lambda_3 < 0$.

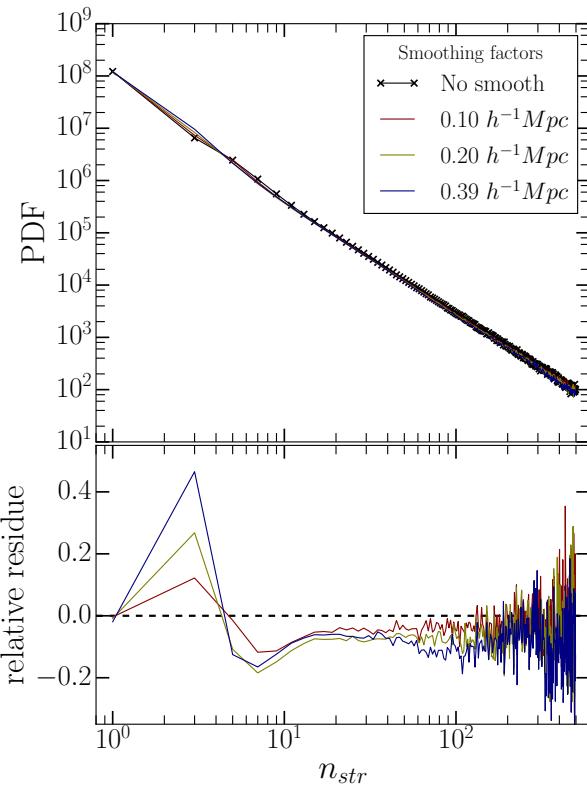

Figure 10. Probability distribution function of the multistream n_{str} values in the simulation box with $N_p = 256^3$. The multistream field is calculated at refinement factor $l_l/l_d = 2$. Unsmoothed multistream field is compared with different Gaussian filtering scales. Softening scales of equal to 0.5, 1, and 2 times the side length of diagnostic grid l_d correspond to $0.10h^{-1}\text{Mpc}$, $0.20h^{-1}\text{Mpc}$, and $0.39h^{-1}\text{Mpc}$ respectively.

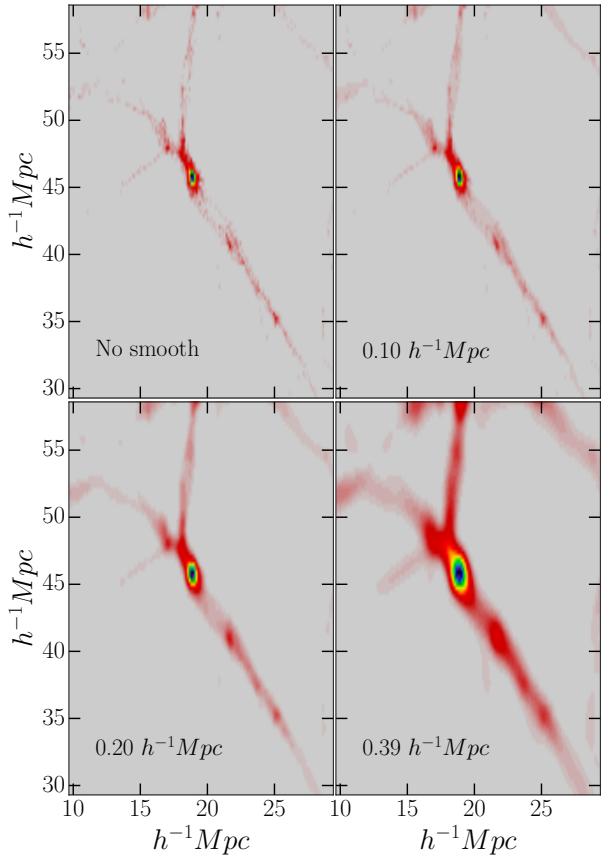

Figure 11. Multi-stream field at various softening scales in the simulation box with $N_p = 256^3$. The multistream field is calculated at refinement factor $l_l/l_d = 2$. Unsmoothed multistream field is compared with different Gaussian filtering scales equal to $0.10h^{-1}\text{Mpc}$, $0.20h^{-1}\text{Mpc}$, and $0.39h^{-1}\text{Mpc}$ respectively.

1.7 per cent at refinement factor of 1 to 3 per cent at refinement factor of 8. Volume fraction of $\lambda_1 \geq \lambda_2 > 0 > \lambda_3$ regions decreases from 5.6 to 4.6 per cent with the increase of refinement from 1 to 8.

In principle, the conditions for geometric criteria are: $\lambda_1 > 0 > \lambda_2 \geq \lambda_3$ for locally flat regions, $\lambda_1 \geq \lambda_2 > 0 > \lambda_3$ for locally tubular structures and $\lambda_1 \geq \lambda_2 \geq \lambda_3 > 0$ for clumped blobs. However, the tabulated the volume fractions in Table 4 does not correspond to cosmic web components themselves. Identification of the components may require post processing steps.

High resolution studies of multistream fields would play an important role in detection of walls and filaments. These two components have smaller length scales along at least one direction with respect to others. As seen in Section 3.1, walls are more resolved in high resolution of multistream fields, enclosing pockets of voids (see Figure 2).

However, a Hessian analysis to identify filaments and walls may be considerably different from that of halo finding due to the following reasons: First, a local geometrical analysis is uniquely convenient for detecting dark matter haloes since they are local structures. Filaments and walls, alternatively, are structures that span over large distances. Secondly, we try to find regions around local maxima of multistream field for haloes. Whereas, filaments and walls

Table 4. Volume fraction of criteria based on n_{str} and λ s of $\mathbf{H}(-n_{str})$ calculated at various resolutions. We chose a smaller slice of $50h^{-1}\text{Mpc} \times 50h^{-1}\text{Mpc} \times 50h^{-1}\text{Mpc}$ i.e., half the volume of the original GADGET simulation box. The refinement factors are the multiplication factors of 1, 2, 4 and 8 times of the native resolution (64^3) of the simulation grid along each axis. Eigenvalues of the Hessian of the field are local geometric parameters. The void is globally defined as $n_{str} = 1$ and the multistream web structure as $n_{str} > 1$.

Global/local conditions	64^3	128^3	256^3	512^3
$n_{str} = 1$ (Void)	90.87	90.92	90.94	90.94
$n_{str} > 1; \lambda_1 > 0 > \lambda_2 \geq \lambda_3$	1.72	2.22	2.67	2.96
$n_{str} > 1; \lambda_1 \geq \lambda_2 > 0 > \lambda_3$	5.60	5.28	4.91	4.57
$n_{str} > 1; \lambda_1 \geq \lambda_2 \geq \lambda_3 > 0$	1.81	1.56	1.37	1.26

have much weaker relationship with local multistream maxima. Filaments and walls usually deviate from flat planar or straight tubular geometries: they often have complicated structures several connections and branches. For these reasons, Hessian eigenvalues alone would not be sufficient in detecting walls or filaments.

6 DISCUSSION

Formation of multiple velocity streams in the context of structure formation has been known in the past, starting from Zel'dovich approximation. Quantification of the multistreams in N-body simulations, however, was recently achieved by [Shandarin et al. \(2012\)](#) and [Abel et al. \(2012\)](#) using the Lagrangian sub-manifold. In our study, the multistream fields are calculated using the tessellation algorithm by [Shandarin et al. \(2012\)](#). We have analysed, for the first time, the local geometry and percolation properties of the cosmic web using this multistream field.

Distinguishing the configuration space into void and non-void is one of the uses of the multistream field. Lagrangian sub-manifold has no folds in the beginning, thus $n_{str} = 1$ uniformly throughout the simulation. Gravitational instability folds the sub-manifold in complicated ways, however, most of the volume has particles without any collapse. [Shandarin et al. \(2012\)](#) and [Ramachandra & Shandarin \(2015\)](#) observed that the single-streaming voids occupy around 85-90 per cent of the simulations at $z = 0$. In this study, we found that the void regions are also connected in a way that the largest percolating void occupies more than 99 per cent of the all the single-streaming regions. Recent study by [Wojtak et al. \(2016\)](#) uses a watershed transform method in the density field prescribed by Lagrangian tessellations ([Shandarin et al. 2012](#) and [Abel et al. 2012](#)) to analyse the evolution of isolated voids. Another recent study by [Falck & Neyrinck \(2015\)](#) on ORIGAMI-voids also reveal a similar percolation at the limit of simulation resolution. They observed persistence of this phenomenon for different resolutions of the N-body simulation. Multi-stream analysis, on the other hand, is not limited to mass resolution of the simulation. Our multistream analysis refined upto 8 times the simulations resolution revealed that the percolation phenomenon still persists. However, at high refinements of the

multistream field, we observed small voids that are enclosed by highly resolved non-void membranes.

Walls are the first collapsed structures in the dark matter Universe. At highly refined multistream field, thin membranes of the structures are often resolved, revealing small voids enclosed by them (compare two top panels in [Figure 12](#)). These preliminary structures are separated from the voids by caustic surfaces. These caustics have volume measure zero, which makes detection of their surface harder in the multistream field, even at very high resolutions. On the other hand, caustic surfaces themselves can be detected using the Lagrangian sub-manifold by identifying the common faces of neighbouring tetrahedra with opposite volume signs ([Shandarin et al. 2012](#)). They are shown in the bottom panel in [Figure 12](#). One can see that increasing the refinement factor from 2 to 8 adds mostly walls but the complete wall structure shown in the bottom panel is still considerably greater. Please note that the plots in two top panels adjusted exactly to the simulation box in Eulerian space, and the bottom plot shows the Lagrangian box mapped to Eulerian space without adjusting to the simulation box.

There are extensive number of topological indicators in the context of density fields or spatial co-ordinates - such as alpha shapes, Betti numbers, genus statistics. Although a comparative study of these topological measures in multistream fields may be interesting, it is not the intent of this paper. In this study, we only investigate percolation transitions in excursion sets of multistreams as a preliminary analysis of topological connectivities. Excursion sets in density fields are shown to have quick percolation transitions ([Shandarin et al. 2010](#)) and a similar trend in multistream field is investigated here.

Excursion sets of multistream and density field (calculated using CIC and DTFE in this study) reveal some of the topological differences. At any volume fraction of excursion set f_{ES} , the filling factor of the largest structure f_1/f_{ES} is lower for mass density (both CIC and DTFE). This concludes that the mass density field is more fragmented than the multistream field. A large number of disconnected segments are seen at high n_{str} or ρ/ρ_b thresholds, and the number of connections increase with decreasing n_{str} threshold.

Global connectivities in the cosmic web is slightly different for multistream field and the density field. The largest structure in the excursion set starts percolating at certain values of excursion volume fraction (f_{ES}). As shown in Section 4, these percolation transitions occur at $\rho_{DTFE}/\rho_b = 5.16$, $\rho_{CIC}/\rho_b = 5.49$ for density fields and $n_{str} = 17$ for the multistream field. The corresponding percolation volume fraction $f_{ES}^{(P)}$ is smaller for multistream fields ($f_{ES}^{(P)} = 0.75$ per cent for multistream field and $f_{ES}^{(P)} = 1.7$ per cent for the CIC-density field $f_{ES}^{(P)} = 2.9$ per cent for the DTFE-density field). This indicates that the percolating multistream filament is over 2 times thinner than that of ρ_{DTFE} and over 3 times thinner than ρ_{CIC} field.

Since the n_{str} field in this study is calculated on regular grids, the boundaries of the structures are not exactly traced. Outlining foldings in the Lagrangian sub-manifolds exactly as shown in [Figure 12](#) or in the flip-flop calculations shown in [Shandarin & Medvedev \(2016\)](#) give point datasets which are considerably more difficult to analyze. However, recent advancements in computational topology - such as the

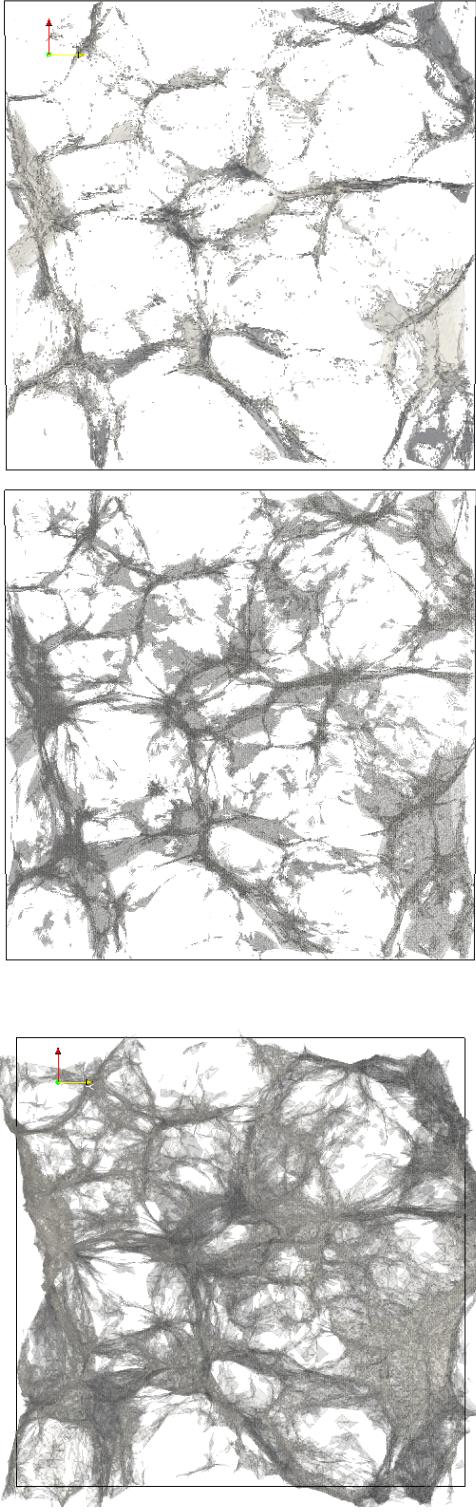

Figure 12. Two top panels show three contours ($n_{str} = 3, 11, 17$) in a slice $100h^{-1}\text{Mpc} \times 100h^{-1}\text{Mpc} \times 10h^{-1}\text{Mpc}$ in the simulation with 128^3 particles, computed at two refinement factors: 2 (upper) and 8 (lower). The bottom panel shows the caustic surfaces in the same slice.

adaptation of the watershed transforms (using SpineWeb - Aragon-Calvo et al. 2008 and Morse theory (using DisPerSe - Sousbie et al. 2011b and Felix - Shivshankar et al. 2015) to inherently discrete datasets may be useful in the topological analyses of flip-flop fields and caustics.

The multistream field is a scalar function of Eulerian coordinates. We have analysed functional variation of the $-n_{str}(\mathbf{x})$ field using Hessian eigenvalues. The Hessian analysis is generally done for inherently continuous fields, For example, Hessian analysis has been previously studied for smoothed density fields (see Sousbie et al. 2008, Aragon-Calvo et al. 2007, Aragon-Calvo et al. 2010, Cautun et al. 2014 etc.), gravitational potential and velocity shear tensor (Hoffman et al. 2012, Libeskind et al. 2013, Hahn et al. 2007, Forero-Romero et al. 2009, Hoffman et al. 2012 and Cautun et al. 2014). Although the multistream field has discrete values by definition, it may be considered smooth for numerical analysis at the scale of grid length of the field. The resulting Hessian eigenvalues characterize the geometry in a four-dimensional hyper-space of $(-n_{str}, x, y, z)$. The boundary of a region with $\lambda_1 \geq \lambda_2 \geq \lambda_3 > 0$ is a closed convex contour in this hyper-space, and thus its projection onto the three-dimensional Lagrangian space is also closed and convex.

Dark matter haloes, being localised structures, are uniquely convenient for our local Hessian analysis. Conditions of $\lambda_1 > 0 > \lambda_2 \geq \lambda_3$ and $\lambda_1 \geq \lambda_2 > 0 > \lambda_3$ also give information about curvature. Hessian eigenvalue analysis at high resolution of multistream fields may be very interesting in understanding the tubular edges of filaments and surfaces of walls at smaller scales.

7 SUMMARY

We studied certain geometrical and topological aspects of the multistream field in the context of large scale structure of the Universe. Several features were found to be considerably different from traditional density fields. The major findings from our analysis are briefly summarized as follows:

(i) We use the multistream field as a proxy for distinguishing of the DM web from DM voids: the web is defined as the regions with number of streams greater than one and thus voids as a single stream regions. The boundary between them representing a sharp transition from one- to three-stream flow regions would be a caustic surface in the density field if the mass and spatial resolutions were sufficiently high. They were clearly seen in 2D simulations by Melott & Shandarin (1989) as well as in 3D simulations by Angulo et al. (2016), Hahn & Angulo (2016), Hahn et al. (2013) and in velocity fields Hahn et al. (2015).

(ii) Regions without any folds in the Lagrangian sub-manifold are mostly connected. These single streaming void regions at $z = 0$ occupy around 90 per cent of both simulations used in this study, most of which belong to a single percolating structure. However at high resolution multistream analysis, we identify a number of isolated pockets that are entirely enclosed by boundary of walls. But these voids are tiny and collectively occupy less than 0.1 per cent of the volume of the simulation box.

(iii) The Hessian components of the multistream field are universally zero in the interior of the void, due to constant

value of n_{str} . Density field need not have zero Hessians since mass density is not unequivocally constant at $z = 0$.

(iv) We studied the global topology of the non-void ($n_{str} > 1$) structure using percolation analysis. A rapid percolation transition occurred in our multistream field at $n_{str} = 17$. The percolating filament in multistream field is thinner than the percolating filament in mass density field.

The Lagrangian sub-manifold contains dynamical information of structure formation. We analysed the multistream field that contains the information of foldings in the sub-manifold. Connectivities in the void and non-void components of the multistream web reveal several details about structure of the Universe that are not probed by traditional density fields. In addition, we demonstrated the use of geometrical features of the multistream field in identifying potential dark matter halo candidates in cosmological N-body simulations.

ACKNOWLEDGEMENTS

This work has been funded in part by the University of Kansas FY 2017 Competition General Research Fund, GRF Award 2301155. This research used resources of the Advanced Computing Facility, which is part of the Center for Research Computing at the University of Kansas. We thank Mark Neyrinck and Mikhail Medvedev for discussions and suggestions. We also thank the anonymous referee for insightful comments on improving this manuscript.

APPENDIX A: THE MULTISTREAM FLOW FIELD IN ONE-DIMENSION

The top panel in Figure A1 shows the velocity multistreaming phenomenon in a one-dimensional collapse. The phase-space (\mathbf{p}, \mathbf{x}) (where \mathbf{p} is the momentum and \mathbf{x} is the co-moving Eulerian coordinate) is single-valued in the linear stage of evolution (at redshift z_{ini}). Non-linear stage of gravitational evolution of the collision-less dark matter particles then results in multi-valued $\mathbf{p}(\mathbf{x}, z)$ at $z = 0$. The mass particles are sparsely distributed outside the region of gravitational collapse, and are denser in the inner streams.

A dynamically equivalent transformation $(\mathbf{p}, \mathbf{x}) \mapsto (\mathbf{q}, \mathbf{x})$ (where \mathbf{q} is the Lagrangian coordinate) shows the Lagrangian sub-manifold in the middle panel of Figure A1.

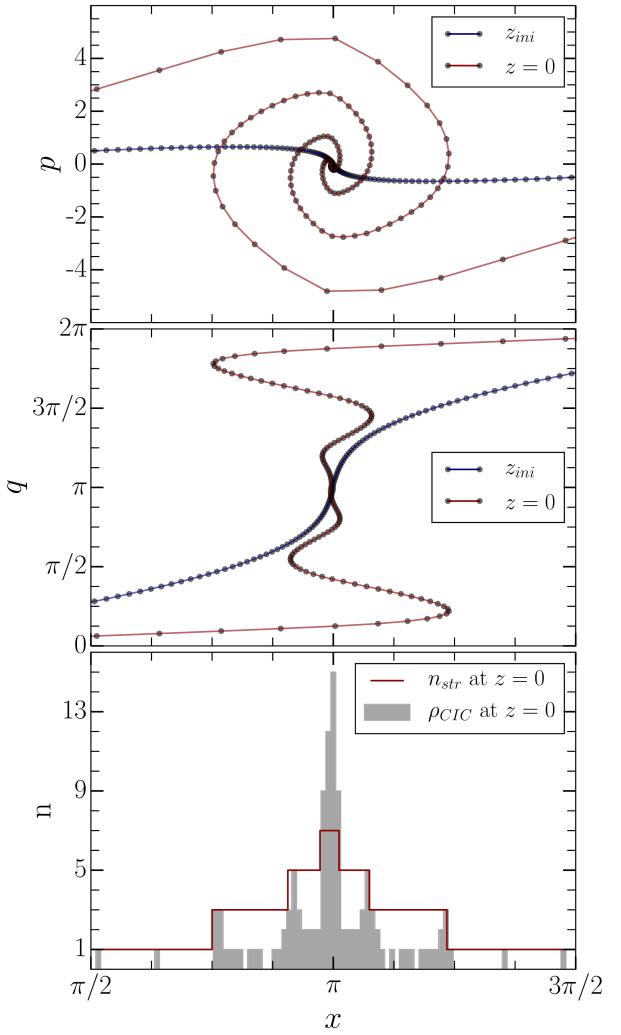

Figure A1. Multi-streaming in one-dimension gravitational collapse. Top panel: (\mathbf{p}, \mathbf{x}) phase-space representation redshift z_{ini} and $z = 0$. Dots represent the dark matter particles. Initially the mass particles are in the linear stage of evolution. At $z = 0$, multiple values of $\mathbf{p}(\mathbf{x})$ is seen in the collapsed regions. Middle panel: Equivalent Lagrangian sub-manifold $\mathbf{q}(\mathbf{x})$. At z_{ini} , the dashed line represents $\mathbf{q} = \mathbf{x}$. Number of streams are parametrized from this sub-manifold. Bottom panel: The multistream field n_{str} and the number-density using CIC algorithm, n_{CIC} at $z = 0$.

This two-dimensional phase-space has foldings that correspond to multiple velocity streams, although the sub-manifold itself remains continuous. A projection of the Lagrangian sub-manifold at each point in the configuration space quantifies the number-of-streams. Folding in the sub-manifold are checked for points in configuration space using tessellations. The tessellating simplices in one-dimensional model are just the line-segments whose nodes are the dark matter particles in the Lagrangian space. Dynamical property is accounted for in this phase-space tessellation since labels of the nodes remain intact throughout the evolution; the line segments may shorten, extend or change orientation. Each folding in the Lagrangian sub-manifold increases the number of streams by a factor of two. In three-dimensional simulations, the sub-manifold twists in complicated ways in

a six-dimensional phase space. The number-of-streams in N-body simulations (Shandarin et al. 2012 and Abel et al. 2012) is calculated using Lagrangian/phase-space tessellations. This triangulation is conceptually different from the Voronoi (See Schaap & van de Weygaert 2000 and references therein) or Delaunay (Icke & van de Weygaert 1991) tessellation schemes.

The bottom panel Figure A1 shows the the multistream field $n_{str}(\mathbf{x})$ at $z = 0$. The field only takes the values of 1, 3, 5 and 7 in this scenario. Caustics occur at the folds in Lagrangian sub-manifold, and have a measure zero (study of caustics in one- and two-dimensional evolution is done in Hidding et al. (2014), three-dimensional caustic surface in a cosmological simulation is shown in Figure 12). Several properties of the multistream field are significantly different from mass density. The bottom panel also shows an illustration of CIC algorithm (cf. Hockney & Eastwood 1988) in calculating density, which is numerically equivalent to counting the number of particles on each cell of a regular grid. One major difference is in the regions before gravitational collapse: n_{str} is universally equal to unity, whereas number density fluctuates. It should also be noted that density by definition is a continuous field; numerical approximations like CIC discrete the field. Alternatively, multistream field is intrinsically a discrete-data field.

APPENDIX B: VARIATIONS IN THE MULTISTREAM FIELD

A second-order local variations of a scalar field f is described by a Hessian. In a three-dimensional domain, the Hessian is given by Equation 1. The geometry of the scalar field is classified by the Eigenvalues of the Hessian. The convex regions have at-most one maxima within the (3+1)-dimensional functional space. Projection of this closed region onto three-dimensional coordinate space also gives a closed surface in coordinate space.

We treat n_{str} approximately continuous, for which the Hessian is always symmetric. In this study we use the scalar field $n_{str}(\mathbf{x})$ inherently has discrete values like 1, 3, 5, and so on. The equation for numerical differentiation in the off-diagonal terms using Forward-difference method (using step-sizes of Δx_i and Δx_j along i and j respectively) is given in Equation B1. Notice that $\frac{\partial^2 f}{\partial x_i \partial x_j} = \frac{\partial^2 f}{\partial x_j \partial x_i}$, since RHS in Equation B1 remains same. Hence the Hessian matrix in Equation 1 for the discrete scalar field n_{str} is always numerically symmetric. Backward or central difference give similar results too. Smoothing of the multistream field further reduces any numerical noise in the Hessian eigenvalues.

$$\frac{\partial^2 f}{\partial x_i \partial x_j} = \frac{1}{\Delta x_i \Delta x_j} [f_{i+1,j+1,k} - f_{i,j+1,k} - f_{i+1,j,k} + f_{i,j,k}] \quad (\text{B1})$$

An integer-valued function, like the multistream field, is either constant or changes by a constant value in its real domain. In addition, the transitions in the multistream field are of multiples of 2, unless caustic surfaces are detected at the exact grid location. Consider $f_{i,j,k} = n$ at any grid point. Due to the property of multistream field, the values in the

neighbourhood differ by a multiple of 2. That is, $f_{i+1,j,k} = n + 2p$, $f_{i,j+1,k} = n + 2q$, $f_{i+1,j+1,k} = n + 2r$, for some integers p , q and r . Thus the second order variation of the multistream field reduces to Equation B2.

$$\frac{\partial^2 f}{\partial x_i \partial x_j} = \frac{1}{\Delta x_i \Delta x_j} [2r - 2p + 2q] \quad (\text{B2})$$

Thus the numerical differentiation is independent of n_{str} itself. It's important to note that this behaviour of the multistream field is independent of grid size. Also, the second order variation is a ratio of an even-number and the face area of the grid cube. The Equation B2 becomes zero in a trivial case of $r = p = q = 0$, which corresponds to regions where n_{str} is constant, including voids. In the non-trivial case, $r = (p+q)$, for non-zero r , p and q . In the multistream grid, $2(p+q)$ could be considered as sum of variations in n_{str} in the immediate neighbouring grid points. And $2r$ is the variation between next closest grid point, which is along the face-diagonal.

On the other hand, mass density fields have sharp peaks at the multistream transitions. These peaks in the at the location of caustic are far less predictable, since the density fields become extremely noisy. For instance, Vogelsberger & White (2011) show noisy peaks of varying magnitude at the at high resolutions of mean density near halo locations. At lower resolutions, these sharp peaks are smoothed out, hence giving the impression of a smooth field. Hahn et al. (2015) show similar ‘ill-behaved’ derivatives in velocity fields at the caustic locations, where the derivatives are infinite.
